## Question 1

This question is about the sampling distribution of the mean, and using  $\bar{X}$  as an estimator for the parameter  $\mu$ . Suppose  $X_1, \dots, X_n$  are independent and identically distributed (i.i.d.) with the same distribution as  $X$ .

a. Recall that  $E[\bar{X}] = E[X]$  and  $\text{Var}(\bar{X}) = \frac{\text{Var}(X)}{n}$ . Do we need to assume anything more about  $X$  for  $\bar{X}$  to be an unbiased estimate of  $\mu$ , and if so, what?

b. One way to write Chebyshev's inequality is  $P(|Y - E[Y]| \geq k\sqrt{\text{Var}(Y)}) \leq 1/k^2$ . Let  $Y = \bar{X}$  and write this inequality out in terms of  $\bar{X}, E[X], k, \text{Var}(X)$ , and  $n$ .

c. If we let  $k = \sqrt{n}$ , the answer from the previous part should simplify to  $P(|\bar{X} - E[X]| \geq \sqrt{\text{Var}(X)}) \leq 1/n$ . If we want 99% probability that the sample mean is *within one standard deviation* of  $X$  away from  $E[X]$ , how large of a sample do we need?

d. Suppose  $\bar{X}$  is unbiased:  $E[\bar{X}] = \mu$ . Compute the mean squared error of this estimate,  $\text{MSE}(\bar{X})$ .

e. Assume now that  $X \sim \text{Ber}(p)$ . For some constant  $c$ ,  $c\bar{X}$  has a distribution that you know. What is the constant, and what is the distribution?

## Question 2

This question will guide you through a *simulation study* in R to understand the bias of a certain estimator. Suppose  $U_1, \dots, U_n$  are independent and identically distributed as  $U[0, \theta]$ , with  $\theta = 1$  and let  $\hat{\theta} = \max\{U_1, \dots, U_n\}$ . Since we are generating this data ourselves, we know the true value of  $\theta = 1$ , so we can compute the bias of  $\hat{\theta}$ . Our goal will be to study how this bias decreases as the sample size  $n$  increases.

The following code creates a *function* that you can use to generate observations of  $\hat{\theta}$ .

```
theta_hat <- function(n) return(max(runif(n)))
```

You need to run this code once so that R learns the definition of `theta_hat`. After that, you can “call” the function by running, for example, `theta_hat(10)` to generate one observation of a maximum of sample size  $n = 10$ .

```
theta_hat(10)
```

```
## [1] 0.9256187
```

To generate a sample of many i.i.d. copies of  $\hat{\theta}$ , we use the `replicate` function:

```
replicate(10, theta_hat(10))
```

```
## [1] 0.9430412 0.6704973 0.9251242 0.9250904 0.9481622 0.9859685 0.7809969
```

```
## [8] 0.9843299 0.9014333 0.7587982
```

Finally, we estimate the bias by generating many samples of  $\hat{\theta}$ , taking their average, and subtracting  $\theta$ :

```
mean(replicate(10000, theta_hat(10))) - 1
```

```
## [1] -0.09095854
```

a. Run this code again to estimate the bias when  $\hat{\theta}$  is based on a sample of size  $n = 100$ , and again for a sample of size  $n = 1000$ .

```
# write code here and delete this comment
```

b. Compute these answers to the answer I gave in class: compute  $(n - 1)/n - 1 = -1/n$  for the same values of  $n$ . Are the simulation estimates of bias reasonably close to the exact mathematical answer?

c. Use the `sd` function to estimate the standard deviation of  $\hat{\theta}$  based on  $n = 10$  and on  $n = 100$ .

```
# write code here and delete this comment
```
